Description

Method of data transmission in a communication network
with a ring configuration

5

The invention relates to a method of joint data
transmission of digital source data and control data
between data sources and data sinks, which are subscribers
of a uni-directionally operated communication network
10 having a ring configuration.

15

Methods of this type are used everywhere today where
electronic and electrical devices of various types that
are intended to exchange information with one another for
the purpose of data communication are connected to one
another, in a sometimes complicated way, by means of data
lines and control lines. For instance, in the audio
sector for example, the data communication between data
sources networked with one another on the one hand - for
20 example CD players, radio receivers, cassette recorders,
microphones - and the data sinks connected to them on the
other hand - for example amplifier-loudspeaker
combinations - can be controlled by a method described
above.

25

30

The network subscribers of various types of such a
communication network are connected to one another by data
lines in such a way that the data stream passes each of
the subscribers of the communication network one after the
other. This produces a communication network with a ring
configuration, with particular advantages in particular
for mobile applications, for example when used in a motor
vehicle, or when used in the household, for example a
multimedia network. The data transmission typical for the
35 method stated above permits a simple connection of data
sources and data sinks, which typically send and receive

data continuously. The data transmission usually takes place synchronously with respect to a clock-pulse signal, since the quality requirements today, for example in the automotive sector, can generally only be met with acceptable expenditure by synchronous data transmission.

In the case of many communication networks, the network subscribers have the same sampling frequency and the same data width as the communication network. In the case of data transmission, a subscriber acting as a data source provides sampled data and transmits them in the form of a bit group to a corresponding data field of the communication network. An addressed network subscriber can subsequently read out this bit group that has just been sent via the communication network.

However, many communication networks having a ring configuration are increasingly expected to meet the requirement that their sampling frequency is very much greater than the respective sampling frequency of the network subscribers. Such a communication network is that known as the MOST network (Media Oriented Synchronous Transceiver Network), which is used in particular in the automotive sector and typically has an integral multiple of the sampling frequency of the connected subscribers. Here, in each case a network subscriber with a low sampling frequency transmits data to the MOST network. Since the sampling rate of the subscriber is a fraction of the sampling rate of the network, after the data transmission of a data burst of the sending network subscriber, the communication network is not fully utilized for the remaining duration of a time interval that the sending subscriber requires. During this time, however, the communication network is blocked for the other network subscribers, as a result of which utilization capacity of the communication network is given

away. The utilization of the communication network is in this case only at most a corresponding fraction of its maximum data transmission capacity.

- 5 The present invention is therefore based on the object of providing a method of joint data transmission of digital source data and control data between data sources and data sinks that are subscribers of a uni-directionally operated communication network having a ring configuration which
10 allows more efficient utilization of the data transmission capacity.

According to this invention, this object is achieved by a method of data transmission with the features of patent
15 claim 1, that is to say by a method of the generic type

in which source data and control data are transmitted in a format which prescribes a clocked sequence of individual bit groups of the same bit width which are transmitted in a continuous data stream, in each case
20 specific bit positions predetermined by the format are reserved,

in which the subscribers sample data in each case with a first sampling frequency and the communication network samples data with a second sampling frequency,
25 which is an integral multiple of the first sampling frequency,

in which, within each bit group, at least one contiguous region with a predetermined number of bit positions can be reserved for source data and the
30 contiguous region(s) in each case have a beginning and a defined length and are in each case assigned to a subscriber address,

in which at least one contiguous region within a bit group is in each case assigned a significant bit position,
35 which in the case of one of the subscribers is set to a first logic level and in the case of all the other

subscribers is set to an opposed, second logic level.

With the present invention it is possible to bring about a higher efficiency in the data transmission by making it possible to ensure that theoretically all the subscribers connected to the communication network can transmit data via the communication network simultaneously. In this case, the communication network can be utilized very effectively.

10

The present invention is suitable in particular for a communication network in which the sampling frequency of the connected subscribers is synchronized with the sampling frequency of the network. It would of course also be conceivable for these sampling frequencies not be synchronized with one another, but for the second sampling frequency to have any desired phase shift with respect to the first sampling frequency. This arbitrary phase shift, which may be, for example, 10% of the period of oscillation of the second sampling frequency, ensures greater flexibility in the data transmission. In this case, however, the subscriber receiving the data, for example a transceiver, should comprise means for data buffering.

25

The description, which follows, of the method according to the invention was described on the basis of a specially designed communication network, to be specific a MOST network with four or eight connected subscribers, which in each case have a sampling frequency four times lower than the sampling frequency of the communication network. Advantageously, any desired number of the subscribers mentioned above may also be connected to the communication network. In addition, the sampling frequency of the communication network may advantageously also have any desired multiple of the sampling frequency of the

35

connected subscribers.

In an advantageous embodiment, a significant bit is provided, defining a significant subscriber of the communication network, whereby all the other subscribers
5 are likewise uniquely determined on account of the ring-like configuration of the communication network. This significant bit is formed in the present exemplary embodiment as an LSB-Bit, but may also be formed as any
10 other desired bit position.

The communication network is suitable particularly advantageously for the data transmission of audio signals, since in particular the efficient utilization of the communication network is to be preferred at the expense of
15 a single bit position. The loss of this single bit position can be tolerated in particular in the case of audio signals, since here there is only a slight loss in the quality of the data read out.

20 The method according to the invention is suitable particularly advantageously in a communication network designed as a MOST network, which is typically used in a motor vehicle or else in the household.

25 Further advantageous embodiments and developments of the invention can be taken from the dependant claims, the following description and the figures.

The invention is explained in more detail below on the basis of the exemplary embodiments indicated in the
30 figures of the drawing, in which:

Figure 1 shows a ring-shaped communication network with four network subscribers;

35

Figure 2 shows the data transmission format used for the

method according to the invention in a ring-shaped communication network;

5 Figure 3 schematically shows the data transmission in the case of four subscribers by means of a communication network with four times the sampling frequency;

10 Figure 4 schematically shows the data transmission in the case of eight network subscribers by means of a communication network with four times the sampling frequency.

15 In all the figures of the drawing, similar or functionally similar elements have been provided with the same reference numerals.

20 Figure 1 shows a ring-shaped network 1, which in the present case is designed as a MOST network. The network 1 comprises four network subscribers 10, 11, 12, 13, one of the subscribers 10 being designed as a clock generator. The four subscribers 10, 11, 12, 13 are connected to one another in the form of a ring via uni-directionally operable data lines 14, 15, 16, 17 in such a way that a
25 data stream can take place clockwise from one subscriber to the other 10, 11, 12, 13. The physical direction of the data transmission has been represented in figure 1 by arrows on the data lines 14, 15, 16, 17.

30 Figure 2 shows the data transmission format used for the method according to the invention in a ring-shaped communication network corresponding to figure 1. In figure 2, a bit group, which is also referred to as a frame, is denoted by 2.

35

In the present exemplary embodiment, the bit group 2

comprises 64 bytes, that is to say 512 bits, which is an integral multiple of the lengths of bit groups in known transmission formats for synchronous data, so that compatibility with these formats is provided on account of
5 the simple convertibility. The bit group 2 may, however, also have any other desired bit size.

The bit group 2 contains a preamble 21, which contains in particular data enabling a PLL circuit of a network
10 subscriber to synchronize to a clock pulse received.

The preamble 21 is adjoined by a data field 22 for synchronous data. The data field 22 may be - but does not necessarily have to be - subdivided into several bit
15 subgroups 23 of the same data width, which are in each case assigned to a specific subscriber. This assignment between the bit subgroups 23 and the respective subscribers is typically likewise defined in the preamble 21. The data field 22 in figure 2 has in the present
20 exemplary embodiment two bit subgroups 23. At least one of the bit subgroups 23 has at the least-significant bit position 23a a single bit position that is also referred to hereafter as the LSB 23a (Least Significant Bit). This
25 single bit position 23a may, however, also be arranged at any other desired location of the bit subgroups, for example at the most-significant bit position (MSB, Most Significant Bit).

The data field 22 for synchronous data is typically
30 adjoined, but not necessarily, by a further data field 24 for asynchronous data. This data field 24 for asynchronous data serves the purpose of permitting the most flexible data transmission possible between the subscribers, in which the data width of the data to be
35 transmitted has a variable width. The data field 24 is adjoined by a check and control field 25, which has, inter

bcr140

- 8 -

alia, check and control bits for controlling the data transmission.

5 The bit group 2 represented in figure 2 has not been represented to scale for the sake of a clear representation.

10 To be able to transmit data in a communication network corresponding to figure 1 between the multiplicity of subscribers 10, 11, 12, 13 connected to one another, a region within a bit group 2 which is reserved for the source data transmitted in a continuous data stream may be subdivided into a plurality of bit subgroups 23 of the same length, it being possible for the source data
15 attributed to each bit subgroup 23 to be assigned to a specific subscriber 10, 11, 12, 13 in accordance with the control data.

20 The exact method of data transmission according to the invention in a communication network having a ring configuration is explained in more detail below with reference to figures 3 and 4. For the sake of better clarity, the fields 24, 25 arranged after the data field 22 and shown in figure 2 are not represented in figures 3
25 and 4.

Figure 3 shows on the basis of eight bit groups 2 sent one after the other via the communication network 1, that is to say frame n to frame n+7, the method of data
30 transmission according to the invention with four network subscribers 10..13. For the data transmission method represented in figure 3, a communication network corresponding to figure 1 is used, that is to say a communication network 1 with four connected subscribers
35 10..13. The data transmitted by the subscribers 10..13 have a data width of 16 bits. The sampling frequency f1

of the communication network 1 in the present exemplary embodiment is four times as high as the sampling frequency f_2 of the subscribers 10..13. Since the sampling frequency f_2 of the subscribers 10..13 is consequently approximately one-quarter of the sampling frequency f_1 of the communication network 1, the data of a specific subscriber 10 can be transmitted with every fourth bit group 2. In the interim time, the remaining three subscribers 11..13 can transmit data on the same position of another bit group 2. In this way, a data transmission effectively takes place in each of the four successive bit groups 2.

However, only fifteen bits can be used here for data communication, since the LSB 23a is required for identifying a significant subscriber 10. For identification, the LSB 23a in the case of this significant subscriber 10 is set to a high logic level "1", while the LSB 23a in the case of the other subscribers 11..13 is set to an opposed, low logic level "0". This procedure ensures that the individual subscribers 10..13 and consequently the corresponding data can be unequivocally identified on account of the unidirectional data transmission of the communication network 1 designed in the form of a ring. Although one bit is lost here for the data transmission, this is acceptable, since a comparatively very much higher efficiency of data transmission can be ensured by the method according to the invention.

30

In addition, in particular in the case of the data transmission of digitally sampled audio signals, as typically takes place in the case of the MOST networks mentioned at the beginning, it is possible to dispense with a single bit in the data transmission without having to accept a significant loss in quality as a result.

35

Figure 4 shows a further-developed method of data transmission, in which not only the 15-bit wide data field 23, which is identified by the LSB 23a, but also a
5 separate, second data field 23, which is 16 bits wide, is transmitted within a bit group 2. The corresponding communication network 1 may in this case be designed for up to eight subscribers 10..17. For this second data field 23, preferably no LSB 23a is required for
10 identification, since, when a single subscriber 10 is unequivocally identified, as already mentioned above, all the subscribers 10..17 are unequivocally identifiable on account of the ring-shaped structure of the communication network 1, which is uni-directionally operated. In this
15 case, subscriber 10 is unequivocally identified by means of the LSB 23a, which has been set to "1". The other subscribers 11..17 of the communication network 1 are consequently likewise uniquely determined, for example subscriber 10 together with subscriber 14, subscriber 11
20 together with subscriber 15, etc. The subscriber 10..17 receiving data consequently only has to determine the appearance of the LSB 23a set to "1" for the subscriber 10 and count the corresponding subsequent bit groups 2 to be able to read out the data of the correspondingly desired
25 subscriber 10..17.
